## 1 INTRODUCTION

Nowadays, many people face problems related to bone disorders. Bone tissue is able to completely regenerate by itself if the damaged part is small enough. If not, it is necessary to help bone restore its damaged part by using bone grafts. The most suitable properties naturally have autografts, i.e. parts of bone harvested from the patient's own body, however there is a lack of available tissue material and the necessity of two surgical procedures causes problems. However, the demand of bone graft is huge - a few million people need a bone graft each year [1]. Hence, a development of a new type of synthetic graft, further referred as scaffold, seems to be a promising way.

The requirements on scaffolds are manifold [2]. The ideal scaffold must be biocompatible (e.g. must not elicit an inflammatory response nor demonstrate immunogenicity or cytotoxicity). It should support tissue formation by three dimensional structures with pores allowing cells to migrate throughout the material and support vascularization of the ingrown tissue. Pores must be interconnected with pore size minimally 100  $\mu\text{m}$  in diameter (ideally about 150 - 500  $\mu\text{m}$ ) [3, 4]. Besides macropores, microporosity of the walls (< 100  $\mu\text{m}$ ) is desirable because it provides a larger surface area which is significant for protein adsorption, cellular adhesion and proliferation [4]. Scaffolds should be further able to create a stable interface with the host bone without fibrous connective tissue. Its surface texture should promote cell adhesion and adsorption of biological metabolites [5]. In addition, it should support cell differentiation and proliferation [6]. Over a few months' time, the scaffold ought to resorb in the body environment. Resorption kinetics should be equal to the bone repair rate in order to facilitate load transfer to developing bone. The by-products must not be toxic and should be easily eliminated via the respiratory or urinary systems [7]. Mechanical properties must be sufficient and the scaffold must not collapse during handling and in vivo during the normal physical activities. Mechanical properties should be ideally similar to host bone. The optimal Young's modulus of cellular scaffold should be in range 0.1–2 GPa. Compressive strength should be 2 to 20 MPa. Scaffolds should be easily manufactured in desired shapes which would match the defect in the bone. Hence, the intrinsic structure as well as the composition plays critical roles in the success of a scaffold.

## 2 AIMS OF THE THESIS

This thesis aims to contribute to the search for a suitable bone substitute. The main goal was to prepare porous ceramic materials with sufficient mechanical and biological properties that could potentially serve as substitutes of hard tissues. To solve this goal, research was divided into the following steps:

- 1) Development of ceramic foams with hierarchical porosity up to pore sizes 1500  $\mu\text{m}$  via replication technique. One approach included composite ceramic scaffolds with enhanced mechanical stability due to strong bioinert core based on alumina and/or zirconia. The second approach was focused on development of fully bioactive ceramic scaffolds based on calcium phosphates.
- 2) Development of bioactive scaffolds by burning out the organic compounds from in situ blown polyurethane / calcium phosphate composite.
- 3) Study of mechanical and biological properties of the prepared scaffolds.

### 3 EXPERIMENTAL

#### MATERIALS

Commercial reticulated polymer foams Bulpren (Eurofoam, Czech Republic) of five different pore sizes (30 to 90 ppi, pores per inch) were replicated.

Three different oxides: white fused corundum F1200 (Koltex, Czech Republic), synthetic alumina RC HPDBM (Malakoff Ind., US), Yttria stabilized zirconia HWY5.5 SD (Guang Dong Huawang Materials, China) and two calcium phosphate commercial powders hydroxyapatite and beta-tricalcium phosphate (both Fluka, Switzerland) were used. Powders were bonded by polymeric binders (PVA – Mowiol or PVB – Butvar) or by colloidal solutions (1) AlOOH sol Disperal P3 no.10090 (Condea Chemie GmbH, Germany) or (2) colloidal silica Ludox SK-R (Grace, U.S.). Besides powders and binders, other additives such as plasticizers (Glycerol (Onex, Czech Republic), deflocculate (Dolapix CE64 (Zschimmer Schwarz, Germany) or defoaming (n-Octanol (C<sub>8</sub>H<sub>18</sub>O, Lachema, Czech Republic) agents were added to prepare stable suspensions.

Diisocyanate Ongronat® 2500 MDI (BorsodChem Zrt., Hungary) and polyol Stepanpol PS-2412 (Stepan Company, US) were used for in situ blown polyurethane /calcium phosphate composites.

#### METHODOLOGY

Powders, suspensions and sintered scaffolds were characterised by following methods: *Specific surface area* was evaluated via nitrogen adsorption by ChemBET 3000 (Quantachrome, USA) device. *Particle size distribution* by laser diffraction on LA 950 (HORIBA, Japan) device. *Thermal analysis*, was performed by 6300 Seiko Instruments TG-DTA in argon or air/argon (1:1) mixture, flow rate 400 ml / min, ↑2 °C/min. *Zeta potential* was measured in aqueous dispersions by using Zetasizer 3000 HS (Malvern Instruments, UK). *Viscosity* of the prepared sols and slurries was measured using a rotary rheometer Mars II Haake (Thermo Scientific, US). *Phase composition* was determined by X-ray diffractometers SmartLab 3kW (Rigaku, Japan) and PANalytical X'pert (Philips, Netherlands). The *morphology* was observed using scanning electron microscopy (ZEISS Ultra Plus, Germany, Tescan VEGA TS5136XM, Czech Republic and Philips XL30, Netherlands).

*Total porosity* of scaffolds was calculated as follows [8]:  $P = \frac{\rho_t - \rho_b}{\rho_t} \times 100\%$ , where  $\rho_t$  is the theoretical density and  $\rho_b = \frac{m_b}{V_b}$  is the bulk density,  $m_b$  is the mass of the dry test piece and  $V_b$  is the total geometrical volume. The bulk density of struts was determined via Archimedes' principle (EN 623-2) with distilled water [8]. Image analysis was performed to determine the porosity of struts, the total porosity and pore (cell) sizes and their distribution. The true 3D mean pore diameter was from 2D values recalculated by simple stereological correction factor 0.785 [9].

*Mechanical properties* of prepared foams were determined using a compression test by high-precision Electric Actuator Systems 8862 (Instron, US) equipped with 5 kN load cell. The crosshead speed of 0.5 mm/min was used for loading in all tests. The compressive strength was determined from the maximal obtained force.

*Bioactivity* was tested in SBF solution according to Kokubo recipe [10]. *Cytotoxicity* of materials was tested *in vitro* using direct contact assay according to EN ISO 10993-5 specifications [11] with cells of cell line MG-63 (3500 cells/cm<sup>2</sup>). *Cell viability* was tested with

adipose-derived stem cells which were isolated from adipose tissue by centrifugation and collagenase extraction, as described in [12]. Cells were trypsinized and seeded on materials at concentration of 50.000/100  $\mu\text{l}$  for analysis cell viability and 1 million cells/100  $\mu\text{l}$  for evaluation of cell morphology. Samples were taken for analysis after 24 hours of cultivation. Cell viability was assessed by live/dead assay. Cells cultivated for 24 hours on all materials were fixed and permeabilized. Actin cytoskeleton was stained with Phalloidin Rhodamine (R415, Lifetech, Czech Republic) dissolved in PBS and cell nuclei were stained with 4',6-diamidino-2-phenylindole (DAPI). Samples were observed with epifluorescence microscope Cell<sup>^</sup>R (Olympus C&S Ltd., Czech Republic).

**CERAMIC FOAM PROCESSING:** Ceramic scaffolds were prepared by two techniques: by polymer replica technique and by burning out polyurethane from CaP / PU composites blown in situ from MDI and polyol. By means of replica technique, scaffolds were prepared according to scheme in Fig. 1

**Fig. 1** A scheme of preparation of ceramic scaffold by replication technique: (a) PU template, (b) template coated by suspension, (c) sintered ceramic body

Chemical composition of suspensions, heat treatment and other parameters are described in more detail below.

*Alumina based scaffolds:* 6 wt.% boehmite sol was after 24 h of aging filled with fused alumina powder (71 to 73 wt. %). The PU foam of initial porosity 30 ppi was used as template to replicate. After heat treatment (800 $^{\circ}\text{C}$  / 2h,  $\uparrow$ 1  $^{\circ}\text{C}/\text{min}$  and 1600  $^{\circ}\text{C}$  / 2 h,  $\uparrow$ 5  $^{\circ}\text{C}/\text{min}$ ), the struts were soaked in 8 wt= Dispersal sol for 24 h, 48 h, 168 h and 5 $\times$ 5 h, or were coated by suspension composed of Dispersal sol filled with synthetic alumina. Scaffolds after the second sintering (1600  $^{\circ}\text{C}$  / 2 h) were coated by hydroxyapatite suspension ball milled in 2% solution of Butvar in IPrOH. The polymer was burnt at 800  $^{\circ}\text{C}$ /2 h and composite sintered at 1250  $^{\circ}\text{C}$ /2h in air atmosphere.

*Alumina toughened zirconia based scaffolds:* Dispersal sol was stabilised to pH 4.0 and after 24 h of aging was filled by zirconia powder. The concentration ratio between boehmite sol and zirconia was calculated for alumina concentration (2.5, 5, 10 wt.%) in composite after sintering. Suspensions contained from 50 to 60 wt. % of solid phase. To achieve different porosities, various number of layers was applied on PU template (45, 60 ppi). The coating and drying procedure was repeated until the desired number of layers was reached (up to 6). Foams sintered at 1550  $^{\circ}\text{C}$  for 2 h in air were coated by suspension containing hydroxyapatite

or beta–calcium phosphate and 2wt. % of Butvar. Composites were sintered at 1200 °C/3h in air.

*Calcium phosphate based scaffolds:* suspensions were prepared from polyvinylalcohol Mowiol 10-98 (5 wt. %) dissolved in water, 0.05 wt. % octanol, 0.3 wt. % glycerol and at 800 °C calcined hydroxyapatite powder (40 to 50 wt. %). PU templates of 45, 60, 75 and 90 ppi were burnt out at 1000 °C/ 2 h with heating rate 0.5 °C/min, scaffold was finally sintered at 1200 °C in air.

*Calcium phosphate based scaffolds reinforced by silica:* hydroxyapatite was bonded by colloidal silica solution Ludox. 5, 10, 15 and 20 wt. % concentration of silica were tested. Powder was added into the water and Ludox mixture. The resulting suspension was agitated by 3D motion generated by Turbula device (Willy A. Bachofen AG, Switzerland) at 98 rpm for 2 h. Suspension was applied on PU templates of porosities of 60, 75 and 90 ppi. Foams were after drying heat treated at 1000°C / 2h and sintered at 1200 or 1250 °C.

*Calcium phosphate scaffolds prepared from rigid polyurethane foam:* Cellular polyurethane / CaP composite scaffolds were blown by the reaction between the polyisocyanate ONGRONAT 2500, the polyol STEPANPOL PS-2412, deionized water and hydroxyapatite powder. The effect of mixture loading (CaP / PU ratio of 0.4–1.2), added water (0–5 pphp, parts per hundred parts of polyol) and isocyanate index (0.75 to 1.25, preferably set to 1.05) was evaluated. Composite scaffolds were prepared in two steps: (1) polyol, water and powder were mixed, (2) the isocyanate was added afterwards. The resulting mixture was immediately put into a mould and left there for 24 hours to allow the formation and growth of the composite foam. The scaffolds were shaped after 24 h hardening. The organic contents were burnt out in air at 800 °C for 2 hours (or 1050 °C/2 h) with 0.5 °C/min heating rate. Sintering was conducted at 1050 °C/2 h, 1200 °C/2 h and 1350 °C/2 h in air atmosphere.

## 4 RESULTS AND DISCUSSION

### 4.1 Bioactive ceramics based on alumina core

#### *Characterization of suspensions*

The rheological behaviour of sols and suspensions was studied in order to find suspension with optimal adhesion to PU template, optimum stability and high cover efficiency. Fig. 2a illustrates how time of aging influenced viscosity. The viscosity decreased with increasing time of aging. The shear thinning behaviour occurred in lower shear stresses in the case of shorter aging time (2 and 4 h). The optimal aging time was determined to be 24 h, when the supposed de-agglomeration of powder was finished and sol was stabilised with almost Newtonian rheological behaviour.

As shown in Fig. 2, the suspensions with various alumina content (from 71 to 73 wt. %) exhibited shear-thinning behaviour in accordance with published works [13, 14]; viscosity increased with increasing alumina content. Suspension with 72.5 wt. % of alumina revealed an optimal adhesion to PU foam with low degree of sealed struts of foam.

**Fig. 2** Rheological behaviour of (a) 6 wt. % dispersal sol, (b) alumina suspensions

#### *Foam morphology*

The macrostructure morphology of prepared foams after taking into account the shrinkage was almost the same as one of PU template that was replicated. As is evident from Fig. 3 prepared foams were highly porous without sealed walls of scaffold cells (pores). The average scaffold cell size was  $3539 \pm 218 \mu\text{m}$ . The average size of pores that connected cells, sometimes referred as “cell windows” was about  $1200 \mu\text{m}$ . Thickness of hollow struts varied between 260 and  $370 \mu\text{m}$ . The triangular void in the centre of strut (see Fig. 4a) was a main drawback of replica method, because it negatively influenced the mechanical properties of the foam [15]. The total porosity of prepared samples achieved 95%, the porosity of material of struts was almost 50%. This porosity slightly decreased with increasing alumina content. Results indicate that long soaking time had a positive influence on density of strut material.

**Fig. 3** Macrostructure of alumina foam (A7250)

Influence of infiltration of Disperal sol on struts morphology is illustrated in Fig. 4. It is evident that the hollow voids inside the struts were not completely filled with nanosized alumina (Fig. 4b), On the contrary, the strut was completely filled by second approach, by coating by microsized synthesized alumina (Fig. 4c)

**Fig. 4** Cross-section of alumina core: (a) after sintering, (b) after soaking in Disperal sol for 5 × 5– newly formed small alumina particles are visible in pores, (c) Detail of core strut filled by synthetic alumina

This alumina / alumina scaffold was coated by hydroxyapatite suspension to improve biological properties. Fig. 5. shows the layers are strongly bound to each other. The thickness of each layer (synthesized alumina and hydroxyapatite) was about 20 μm.

**Fig. 5** Microstructure of composite (from right to left: alumina core, alumina shell and hydroxyapatite layer)

## Bioactivity

After 14 days of soaking in SBF, the surface of the scaffold was partially covered by newly formed apatite layer in typical cauliflower morphology consisted of thin lamellae as is illustrated in Fig. 6. The formation of bone-like apatite on the surface of alumina / alumina / hydroxyapatite scaffold indicates bioactive behaviour.

**Fig. 6** Surface of alumina / alumina / hydroxyapatite scaffold after 14 days immersion in SBF: (a) typical cauliflower like structure of newly formed apatite; (b) detail of thin lamellae.

## Mechanical properties

The overview of the compressive strength values depended on concentration of alumina in suspension and time of soaking by Disperal sol is plotted in Fig. 7.

**Fig. 7** Compressive strength of alumina foams reinforced by boehmite sol in dependence of various soaking times.

As evident, the short soaking time and/or suspensions with low powder content exhibited low compressive strength due to non-homogenous and insufficient infiltration of the core layer. The optimal processing conditions were powder content of 72.5 wt. % and the soaking time 168 h or 5 × 5 h. Due to high porosity, compressive strength values seemed to be low. By second alumina coating, the porosity of specimens was reduced (mainly due to strut filling) and because strength is exponentially proportional to the porosity, the mechanical stability of the prepared foams was improved (from 0.3 MPa up to 1.2 MPa) as is displayed in Fig. 8.

**Fig. 8** Compressive strength core-shell alumina composites. A725 – alumina core; A725\_R35 – alumina core / alumina shell (35 wt. %); A725\_R50 – alumina core / alumina shell (50 wt. %);

## 4.2 Bioactive ceramics based on alumina toughened zirconia

Bioactive ceramics described in this chapter were composed of zirconia inorganically bonded by boehmite (AlOOH). The amount of alumina in the structure was 2.5, 5 and 10 wt. %. The alumina was added to zirconia because it was reported that it prevents zirconia from unfavourable low temperature degradation in body environment [16]. The amount of alumina produced from decomposition of commercial boehmite was determined via thermal analysis. The total weight loss was 30.5.

### *Characterisation of suspensions - zeta potential*

Zeta potential, a key indicator of the stability of colloidal dispersions was measured in aqueous dispersion of Dispersal P3. Colloids with low absolute value of zeta potential (-30 mV to +30 mV) are not efficiently electrically stabilized and tend to coagulate. As is evident from Fig. 9, the dispersions in acidic range behave stably, the highest  $\zeta$ -potential equalled to +60 mV was measured at pH 4, and therefore the pH of prepared sols was adjusted by acetic acid to this value in the following experiments.

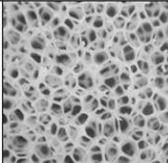

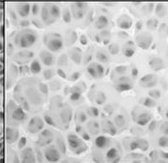

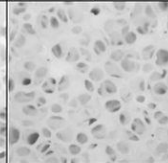

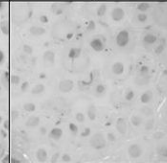

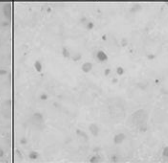

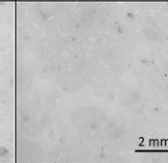

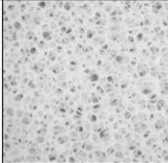

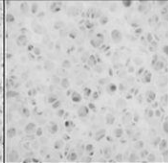

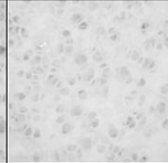

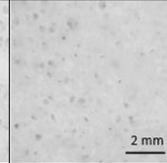

**Fig. 9** Left: Thermal analysis of commercial boehmite sol Dispersal P3; right:  $\zeta$ -potential as a function of pH for the dispersion Dispersal P3.

### *Characterisation of suspensions - rheological properties*

Suspensions were prepared from 24 h aged boehmite sol which rheological properties were described in previous chapter. From a technological point of view, the optimum suspension for coating the scaffold of 45 ppi contained 60 wt. % of solid phase. However, this suspension was too viscous for coating of scaffolds with smaller pores. To avoid undesirable blocking of open scaffold cells (“macropores”), the scaffolds with 60 ppi and 75 ppi porosity were coated by suspension containing 50 wt. % of solid phase.

### *Morphology of sintered scaffolds*

Scaffolds of total porosity (57–98%) were prepared by multiple coating process (up to 6 repeating). Pore sizes of interconnected macroporous scaffolds varied from 350 to 1200  $\mu\text{m}$ . Scaffold cell size corresponded to the cell size of polyurethane foam reduced by shrinkage. With an increasing number of layers, the average thickness of struts grew from 73  $\mu\text{m}$  to 395 nm. The typical reticulated morphology was lost as porosity decreased below 70 % (in the case of larger pores – 45 ppi) and below 80% (for 60 ppi). Overview of macrostructures of prepared scaffolds is shown in the Fig. 10.

	1 layer	2 layers	3 layers	4 layers	5 layers	6 layers
45 ppi						
Porosity:	98.5 %	94 %	88 %	72 %	61 %	51 %
	1 layer	2 layers	3 layers	4 layers		
60 ppi						
Porosity:	97 %	91 %	77 %	60 %		

**Fig. 10** Dependence of porosity on the number of layers.

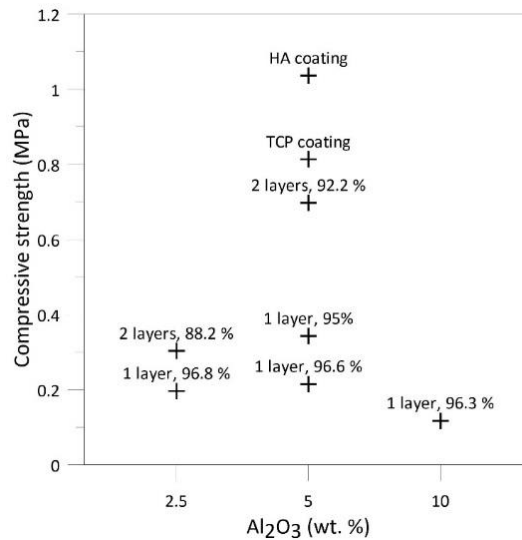

Alumina toughened zirconia substrates with desirable porosity were coated by calcium phosphates suspensions in order to improve the biological properties of scaffolds. Scaffolds consisted of 2 layers of ATZ (5% Al<sub>2</sub>O<sub>3</sub>) and CaP coating are shown in Fig. 11. The thickness of bioactive layer achieved 20 to 60 μm. The struts of ATZ cores were not filled by HA due to closed porosity.

**Fig. 11** Structure of the bioactive coatings: (a) a strut with HA coating; (b) cross section of ATZ scaffold coated by HA; (c) cross section of ATZ scaffold coated by β-TCP.

### *Mechanical properties*

The overview of compressive strength values of ATZ scaffolds containing 2.5 to 10 wt. % of alumina is plotted in Fig. 12. It was confirmed that strength decreases with increasing porosity. Material containing 5 % of alumina exhibited highest strength, so this composition was chosen for subsequent biological testing. All tested samples exhibited strength above 0.2 MPa, the minimal value reported for highly porous cancellous bone [17]. Scaffolds for potential applications in bone tissue engineering should have higher density than at least 2 MPa to ensure sufficient strength to withstand forces generated in the body.

**Fig. 12** Compressive strength of ATZ scaffolds

### *Biological properties – incubation in simulated body fluid*

After 28 days of incubation in simulated SBF the surface was completely covered by a self-grown apatite layer. The top view of ATZ substrate and Ca-phosphates coatings before and after 28 days of soaking in SBF is reported in Fig. 13. No change was observed on uncoated ATZ samples.

**Fig. 13** Microstructure of the substrates and coatings before and after soaking in SBF.

### *Cytotoxicity evaluation*

Although both zirconia and alumina are considered being bioinert in contact with host tissue, the cytotoxicity of the composite was for sure evaluated by direct contact assay. Direct contact between MG-63 cells and all tested materials did not induce any adverse effect, cells retained characteristic morphology of MG-63 cells (see Fig. 14.). SEM was used to study the adhesion and spreading of MG63 cells on the ATZ / Ca-P 3D scaffolds. Micrographs revealed that cells were attached to the pore walls both inside (Fig. 14a) and outside (Fig. 14b) of the 3D structure. These results indicate that cells were able to migrate through 3D structure of composite having the 1200  $\mu$ m large pores.

**Fig. 14** Cell line MG-63 adhered to the scaffold: (a) on inner struts; (b) on outer struts.

This result confirmed that all tested materials (ATZ, HA,  $\beta$ -TCP) were cytocompatible and could be used in tissue engineering applications.

### 4.3 Calcium phosphate scaffolds

Several types of polymer binders were tested in order to achieve a reticulated calcium phosphate foams. However prepared scaffolds had mostly insufficient strength due to high porosity (> 90%). Scaffolds prepared from alcohol suspensions had many defects in the structure, probably as a consequence of fast evaporation of alcohol. The best scaffolds were obtained with water suspension bonded by 5 wt. % of PVA. These results are summarized and compared with silica reinforced scaffolds in the Chapter 4.4.

**Fig. 15** Structure of calcium phosphate scaffolds sintered at 1200 °C/3 h: (a) template 90 ppi, (b) template 75 ppi

### 4.4 Calcium phosphate scaffolds reinforced by silica

The objective of this chapter was to develop a material with higher strength and at least similar biological characteristics as hydroxyapatite. The idea was to prepare ceramic composite material containing calcium phosphate with some reinforcing phase. The choice fell on silica because silicon (as  $\text{Si}^{4+}$  ion) is considered to be one of the essential trace elements required for development of healthy bones. It acts as a biological cross-linking agent in extracellular matrix (ECM). On top of that, it enhances osteoblast proliferation, differentiation and collagen production [18].

#### *Characterisation of scaffolds – processing parameters*

Since polymer replica technique was used, ceramic foams were obtained by burning the polyurethane templates. The thermal analysis was carried out to determine the temperature

at which the complete burnout of the commercial polyurethane occurred in the composite system containing PU (10 wt. %), HA (81 wt. %) and SiO<sub>2</sub> (9 wt. %). According to thermogram which is depicted in Fig. 16 all polyurethane was burned at 550 °C. The shape of exothermic DTA curve in the temperature range 200 to 550 °C indicates that the degradation processes of polyurethane occur by oxidation mechanism.

The total 15% weight loss corresponded to the initial amount of polyurethane in the composite (10 %), amount of adsorbed water (1 %) and to 5% weight loss of commercial hydroxyapatite after its calcination (4 % relative to the composite).

**Fig. 16** TA curves of commercial reticulated PU foam coated by HA-10SiO<sub>2</sub> suspension

### Phase composition

X-ray diffraction patterns indicated that all products of thermal reaction were crystalline. The XRD spectra illustrated that the hydroxyapatite was totally decomposed into  $\alpha$  and  $\beta$ -TCP even at 1200 °C. Traces of tetracalcium phosphate identified in the structure were a result of HA decomposition, according to the following equation [19, 20]:

If the concentration of silica in the tested sample was low (5 wt. %), walstromite (CaSiO<sub>3</sub>), an isomorph of wollastonite, was distinguishable in the pattern. With increasing concentration of silica in the sample, one strong peak at about 21.7° increased. That suggests that silica was transformed to the cristobalite crystalline phase (of P4<sub>1</sub>2<sub>1</sub>2 space group). An approximate weight percentage of phases is listed in Table 1.

**Table 1** Phases present in the scaffolds after heat treatment at 1200 °C (HA) and 1250 °C (HA-SiO<sub>2</sub>)

	$\alpha$ -TCP (wt. %)	$\beta$ -TCP (wt. %)	Cristobalite (wt. %)	Other phases (wt. %) / type	$\alpha$ : $\beta$ -TCP
HA	50.6	49.4	–	–	1.02
HA_5% SiO <sub>2</sub>	60.8	34	2.3	2.9 (walstromite)	1.79
HA_10% SiO <sub>2</sub>	62	25.3	12.7	–	2.45
HA_15 % SiO <sub>2</sub>	59.3	21.1	17.4	2.2 (Ca <sub>4</sub> (PO <sub>4</sub> ) <sub>2</sub> O)	2.81
HA_20 % SiO <sub>2</sub>	65.2	12.5	20.3	2 (Ca <sub>4</sub> (PO <sub>4</sub> ) <sub>2</sub> O)	5.22

Results indicated that the ratio between  $\alpha$ -TCP and  $\beta$ -TCP increased with increasing amount of silica. Various researchers [21-24] confirmed that addition of silica shifted the

temperature of HA  $\rightarrow$   $\alpha$ -TCP transformation to lower value. The stable  $\alpha$ -TCP polymorph could be even formed during sintering above 700 °C [22, 23, 25, 26] [21]. It was further reported that hydroxyapatite sintered in the presence of silica tended to transform to silica substituted tricalcium phosphate (Si- $\alpha$ -TCP) of formula  $\text{Ca}_3(\text{P}_{1-x}\text{Si}_x\text{O}_{4-x/2})_2$  [21, 26].

*Characterisation of scaffold cell size and its distribution*

Fig. 17 and Fig. 18 give an overview of scaffolds with various cell size. Structure of HA scaffold and HA-SiO<sub>2</sub> scaffold was very similar. As obvious from Table 2, pores (defined by cell size) were slightly larger in case of hydroxyapatite.

**Table 2** Pore sizes of HA-SiO<sub>2</sub> and HA

	Cell size (μm)	Size of cell windows (μm)
HA 60ppi	873 ± 55	262 ± 80
HA 75ppi	532 ± 67	204 ± 78
HA 90ppi	385 ± 60	116 ± 45
HA-SiO <sub>2</sub> 45ppi	1150 ± 198	536 ± 113
HA-SiO <sub>2</sub> 60ppi	736 ± 85	287 ± 92
HA-SiO <sub>2</sub> 75ppi	498 ± 58	168 ± 45
HA-SiO <sub>2</sub> 90ppi	375 ± 37	118 ± 35

**Fig. 17** HA scaffolds sintered at 1200 °C/3h; porosity of the PU template: (a) 60 ppi, (b) 75 ppi, (c) 90 ppi

**Fig. 18** HA-10SiO<sub>2</sub> scaffolds sintered at 1250 °C/3h; porosity of the PU template: (a) 45 ppi, (b) 60 ppi, (c) 75 ppi, (d) 90 ppi

### *Biological properties - bioactivity*

Bioactivity of prepared scaffolds was tested in Eagle medium instead of in simulated body fluid Fig. 19 presents the overview of surface morphology of prepared scaffolds before and after immersion in medium. After 3day cultivation in direct contact assay, the surface of scaffolds was covered by newly formed apatite layer. Samples containing silica were fully covered whereas layer of apatite precipitated on pure CaP were not continuous. It could have been caused by high porosity of the sample. Newly formed apatite layer, nucleated under the conditions simulated in vivo indicates a good bioactivity of scaffolds containing cristobalite.

**Fig. 19** Surfaces of HA-SiO<sub>2</sub> scaffolds before and after 3 day incubation in Eagle Medium.

### *Mechanical properties*

Compressive strength of samples with initial pore size 60, 75 and 90 ppi was used for evaluation of the influence of silica content on mechanical properties of scaffolds.

**Fig. 20** Dependence of compressive strength on total porosity

Fig. 20 presents dependence of compressive strength on porosity of HA/SiO<sub>2</sub> scaffolds. Results indicated that strength exponentially increased with increasing density of scaffolds according to the Ryshkewitch-Duckworth [27, 28] equation.

$$\sigma = \sigma_0 \cdot e^{-cp}$$

Where the  $\sigma_0$  is strength at zero porosity,  $c$  is constant (4–7 according to porosity) and  $p$  is porosity.

Silica had a positive influence on the strength, no matter if there were 5 or 20 percent of SiO<sub>2</sub> in HA/SiO<sub>2</sub> scaffolds. Moreover, it seemed that pore sizes also had negligible effect on final strength. One of the requirements imposed on the materials used in tissue engineering are properties similar to those of replaced tissues. In the case of cancellous bone, the compressive strength values were reported between 1.5 to 38 MPa [29], usually 2–20 MPa [30]. Strength-porosity dependence indicated that optimal strength for bone tissue replacement was achieved on the samples with lower porosity than 80%. Therefore compressive strength of the samples reinforced by silica are similar with those of bone and this type of composite material can be potentially used in bone tissue engineering.

#### 4.5 Calcium phosphate scaffolds produced from CaP / PU composite foam

##### *Thermal decomposition of CaP / PU scaffold*

As was mentioned in Chapter 0, ceramic foams were obtained by burning out the polymer from the CaP / PU composites. To determine the temperature at which the thermal decomposition of polyurethanes is finished, the thermal analysis was carried out.

In general, the thermal degradation of polyurethanes in air atmosphere is a complex process involving oxidation of the initial polyol and isocyanate components, which is followed by the thermal decomposition that leads namely to the formation of amines, water and carbon dioxide [31, 32].

TA curves (performed on the sample HA100\_2\_105) are shown in Fig. 21. The total weight loss as a consequence of decomposition was 50 wt. %, which corresponded to the weight content of polyurethane in the input composition. The first endothermic drop on DTA curve below 100 °C was due to water evaporation. Increasing the temperature above 200 °C, the polyurethane started to decompose by a typical two stage process as is evident from the DTG and DTA curves. The weight loss, around 350 °C was caused by the degradation (oxidation) of hydroxyl and amino groups whereas the second stage, around 600 °C was mainly associated with the oxidation of the residual carbon.

Even though the decomposition of organic compounds was completely finished around 750 °C, the CaP / PU composites were heat treated at 800 °C/2 h to ensure the sufficient handling strength of presintered ceramic bodies.

**Fig. 21** TA analysis of polyurethane composite (HA100\_2\_105)

### *Foam characterisation - influence of chemical composition*

Influence of the amount of added water, isocyanate index, ratio between calcium phosphate and polyurethane referred as CaP/PU ratio and sintering temperature on the final morphology was evaluated. Calculated values of total porosity are summarized in Table 3.

**Table 3** Scaffold composition and total porosity at different temperatures

### Effect of added water

Two sets of samples with an increasing amount of added water were evaluated (see Fig. 22). Pictures indicated that water addition (from 0 to 5 pph) had a significant impact on the structure of the composites, mainly on pore size. During the processing water as blowing agent reacted with the NCO-functional groups of diisocyanate and formed unstable carbamic acid which immediately decomposed into an amine and carbon dioxide which caused generation of pores in the structure [33]. Reaction ran according to the following scheme:

**Fig. 22** CaP/PU foams having  $\text{ha/pu ratio} = 1$  and  $I_{\text{NCO}} = 105$  (water content increasing from 0 wt.% (left) to 5 wt.% (right) of polyol)

Theoretically, 1 mol of  $\text{H}_2\text{O}$  would create  $22.4 \text{ dm}^3$  of  $\text{CO}_2$ . If all the created bubbles were stable and remained in the foam, the total volume (and apparent porosity) of the foam would rise with the increasing amount of water. However, this was not experimentally confirmed;

the results summarized in Fig. 23 indicated that apparent porosity was more or less independent on the water content. A slight increase of porosity of samples containing equal amount of powder as polyol was probably caused by different powder to polyurethane ratio, not by water.

**Fig. 23** Influence of water and powder content on porosity calculated from weight, dimensions and theoretical density of hydroxyapatite

Although the total volume of pores was almost the same, the additive water influenced individual pore sizes and their distribution (see Fig. 24 and Fig. 25). Pore sizes were determined by image analysis of polished cross sections cut 3 mm below the top of PU / HA foam, sintered at 1050 °C/2h. All pores having diameter larger than 5 μm were measured on the area 25 mm<sup>2</sup> per one sample. Results are summarized in Table 4. Since the pores were measured in 2D, the real (3D) diameters are larger [9]. Assuming that the pores are ideal spheres and according to the probability of cutting a sphere in different distances far from the largest diameter, the average pore diameters can be simply multiplied by a constant 1.254. This approach is not statistically completely right, detailed explanation of sphere unfolding and particle size distribution in 3D from 2D data can be found elsewhere [34-36].

**Fig. 24** Overview of cross sections of ceramic scaffolds sintered at 1050 °C: top row:  $m_{HA} = m_{polyurethane}$ , from 0 (left) to 5 pphp (right); bottom row:  $m_{HA} = m_{polyol}$ , from 0 (left) to 3 pphp (right)

As is obvious from Fig. 25, the pore size distribution (in 2D) was skewed right, the number of small pores was several times higher than the large ones. For differentiation of the influence of large and small pores which highly probably were not all slices of larger ones, an average size of 10% of the highest measured values was also calculated (see Table 4). It appeared that all of these large pores were interconnected and they formed the greater part of the surface area and they could be suitable for cell colonization.

**Fig. 25** Histograms of measured pore sizes: (a)  $m_{HA} = m_{polyurethane}$ ; (b)  $m_{HA} = m_{polyol}$

**Table 4** Pore sizes estimated from cross section of scaffolds sintered at 1050 °C/2 h

HA/PU	1	1	1	1	1	1	0.62	0.56	0.51	0.47

**Fig. 26** Microstructures of scaffolds with different isocyanate indexes ( $I_{NCO} = 75, 105, 125$ )

HA/PU = 100 %, 2 % H<sub>2</sub>O, sintered at 1350 °C/2 h

#### *Effect of sintering temperature*

The microstructure was changed by the sintering temperature. PU/HA composite had very smooth surface as is evident from left quarter of Fig. 27 (PU+HA), the rough middle part of the same photo is a fracture area where the relief was caused by pulling out of ceramic particles. With an increasing temperature, the grains significantly coarsened and microporosity was reduced.

**Fig. 27** Microstructures of HA100\_2\_105 scaffold sintered at different temperatures: (a) HA/PU composite before calcination; (b) scaffold sintered at 1050 °C; (c) 1200 °C; (d) 1350 °C (the magnification is the same for all 4 photos).

## 5 CONCLUSIONS

Open three-dimensional ceramic scaffolds with interconnected macropores were prepared by polymer replica technique or by polymerization in situ. Ceramic scaffolds were obtained in both cases after burning out the polyurethane and other binders from the structure. Regarding the replica technique, the morphology of scaffolds mimicked the morphology of commercial reticulated polyurethane templates. Cell size and its distribution was controlled by used template. The total porosity was tailored by viscosity of suspension and by number of applied layers.

The first studied system was based on alumina. Open-cell alumina foams were prepared by replica method from nanosized boehmite powder and fused microsized alumina. Highly porous reticulated alumina foams exhibited low compressive strength ( $< 0.25$  MPa) because of high total porosity ( $> 95\%$ ), low microstructure density ( $\sim 50\%$ ) and because of voids inside the struts generated during polyurethane burnout. The strength was at least doubled due to scaffold infiltration by nanosized boehmite, although the struts remained partially unfilled. The successful approach was strut filling by suspension composed of finer alumina particles having allowed about fourfold increase of strength. Mechanical properties were improved, however, material was biologically inert. To shift biological properties to bioactive behaviour, the foams were coated by hydroxyapatite suspension. All components, namely porous core, reinforcing phase (/layer) and bioactive coating, seemed to firmly adhere to each other. For application in bone tissue engineering it would be necessary to reduce pore sizes to maximally  $500\ \mu\text{m}$  and simultaneously improved the compressive strength, e.g. by decreasing total porosity below  $85\%$ .

The second research area dealt with alumina toughened zirconia scaffolds. Macroporous scaffolds with interconnected pores of size ranging from  $350$  to  $1200\ \mu\text{m}$  were prepared by similar way as previously described foams. The difference was that yttria stabilized zirconia was used instead of fused alumina. Based on results of the mechanical testing,  $5\ \text{wt.}\%$  content of alumina was chosen as optimum for further experiments. Scaffolds of various total porosity ( $57\text{--}98\%$ ) were fabricated by multiple coating process (up to 6 cycles). The bioactive behaviour of the composite was achieved by coating of calcium phosphates. Besides bioactivity and cytotoxicity tests, the cell colonization in 3D scaffold was evaluated. It was shown that MG-63 cells grew through the scaffold with  $1000\ \mu\text{m}$  large pores after three-day cultivation, the same amount of cells was found both adhered to the outer and inner struts of scaffold.

The main disadvantage of these two types of scaffolds was the bioinert core. The current trend of tissue engineering are resorbable materials that help bones to regenerate instead of formerly used permanent replacements, so the attention was focused on calcium phosphate scaffolds.

Calcium phosphate 3D interconnected scaffolds with different pore sizes were fabricated with and without silica addition. Pore dimensions ranging between  $375$  and  $1150\ \mu\text{m}$  were depended on the pore size of four templates which were replicated. The average window size between two interconnected pores was from  $118$  to  $536\ \mu\text{m}$ , ideal for cell penetration. Addition of silica ( $5\text{--}20\ \text{wt.}\%$ ) strongly influenced the phase transformation of hydroxyapatite to  $\beta\text{-TCP}$  and  $\alpha\text{-TCP}$ , respectively. The ratio of  $\alpha\text{-TCP}$  to  $\beta\text{-TCP}$  increased fivefold with increasing silica content. Lattice parameters indicated that TCP was substituted by silicate ions. However, almost all amorphous silica was transformed to the cristobalite crystalline

phase. Addition of cristobalite did not negatively influenced the biological properties. Testing in direct contact assay with MG63 cells showed that percentage of covered surface slightly increased with increasing silica content. After three days of cultivation, the surfaces were totally covered by newly formed apatite layer which indicates excellent bioactive behaviour. The cell viability increased with addition of silica; it seemed that silica supported cell adhesion. This trend was followed for the three pore sizes, with the maximum effect noted for the scaffolds using 90 ppi polymer pore size. The main enhancement was, nevertheless, observed on mechanical properties. The compressive strength of calcium phosphate scaffold bonded by polyvinylalcohol was 0.3 MPa at 80% porosity. The strength of silica reinforced calcium phosphates scaffolds exceeded 20 MPa.

From previous paragraph is obvious that preparation of calcium phosphate scaffolds by replica technique was from mechanical point of view less successful. For this reason a novel processing technique was developed to overcome the low strength caused by internal defects and hollow struts. Porous calcium phosphate scaffolds were successfully prepared by polymerization in situ using diisocyanate, polyol and water. Generation of carbon dioxide led to formation of large interconnected pores. Pores smaller than 5  $\mu\text{m}$  were created by polymeric binder burnout during sintering. This small interconnected pores can be convenient for supply of nutrients and oxygen. The total porosity of scaffolds decreased from 99 to 76% as the powder content increased, leading to denser and thicker pore walls between interconnected pores. On the other hand, the total porosity was almost independent on amount of added water (up to 5 pphp, parts per hundred parts of polyol). However, water influenced pore size. Average pore size increased from 65  $\mu\text{m}$  (1 pphp) to 93  $\mu\text{m}$  (5 pphp). Sizes of 10 % of larges pores suitable for cell colonization were enlarged from 234  $\mu\text{m}$  to 539  $\mu\text{m}$  just due to water addition. Because the scaffolds are formed by in situ polymerization, the shape of scaffold can be easily controlled by the shape of mould. The porosity and pore size is tuneable just by powder / polyol / diisocanate / water ratio. On the basis of morphological observations, the calcium phosphate scaffolds could be promising adepts for synthetic bone grafts.

The aim of this thesis, to fabricate three-dimensional scaffolds that can be potentially used in bone tissue engineering, was achieved. Neither of the studied materials was cytotoxic and moreover all prepared composites behave bioactive in simulated body fluid. The most promising adept for application in bone tissue engineering seems to be composite material containing calcium phosphates reinforced by silica.

## ABSTRACT

The aim of this thesis was to prepare three-dimensional scaffolds that can be potentially used for the reconstruction and regeneration of damaged bone tissues. Two techniques were used to create the porous ceramic scaffolds – polymer replica technique and polymerization in situ. A variety of bioceramic materials were studied, mainly alumina, zirconia and calcium phosphates. The effect of processing parameters, such as composition of suspensions, as well as the effect of heat treatment on structure and final properties of the prepared scaffolds were evaluated. Morphology of the sintered scaffolds was characterised by scanning electron microscopy; in particular pore size, pores interconnection, total porosity and density were described. Phase composition, compressive strength and biological properties such as bioactivity and cytotoxicity were also discussed.

The dissertation is divided into several sections. The literature review briefly summarizes the structure and properties of bones, the requirements for scaffolds, advantages and disadvantages of currently used materials and methods of ceramic foam preparation. The first part of experiments dealt with scaffolds prepared by polymer replica technique. All fabricated foams had interconnected pores with size in the range of 300 to 2000  $\mu\text{m}$ , total porosity was 50–99%. The compressive strength of calcium phosphate foams prepared by replica technique reached about 0.3 MPa (at 80 % porosity). Reinforcement of the scaffolds was reached by using bio-inert cores or by incorporation of silica into the composite structure. The strength of calcium phosphate/silica scaffold increased above 20 MPa. The last section of experimental part discusses in situ blown calcium phosphate scaffolds, created by using the formation process of polyurethane foam with diisocyanate and polyol components. The sintered scaffolds had mainly interconnected macroporous structure with pore size ranging 80 to 550  $\mu\text{m}$ . The total porosity was about 76 to 99 %. The advantage of this method compared to the polymer replica technique was that the struts were completely filled.

None of the studied materials was cytotoxic and moreover all studied foams exhibited bioactive behaviour. The most promising adept for application in bone tissue engineering seems to be composite material containing calcium phosphates reinforced by silica.

## ABSTRAKT

Cílem disertační práce bylo připravit trojrozměrné biokeramické podpůrné systémy („scaffolds“), které by v budoucnu mohly pomoci při rekonstrukci a regeneraci poškozených kostních tkání. Porézní keramické pěny byly připraveny dvěma způsoby – replikační technikou a polymerizací in situ. Co se složení týče, byly studovány keramické materiály zejména na bázi oxidu hlinitého, zirkoničitého a kalcium fosfátů. Byl studován jednak vliv procesních parametrů jako je složení suspenzí a jejich viskozit, dále pak vliv tepelného zpracování na strukturu a výsledné vlastnosti připravených materiálů. U slinutých pěn byla pomocí rastrovací elektronové mikroskopie hodnocena zejména morfologie – velikost pórů, jejich propojenost a celková porozita, charakterizace mikrostruktury nebyla opomenuta. Dále bylo stanoveno fázové složení a pevnost v tlaku. Z biologických vlastností byla testována a diskutována bioaktivita a cytotoxicita materiálů.

Disertační práce je členěna do několika částí. V literární rešerši je popsána stavba a vlastnosti kosti, požadavky kladené na kostní náhrady, výhody a nevýhody současně používaných materiálů a způsoby přípravy keramických pěn. Následuje experimentální část, kde byly

nejprve studovány pěny připravené replikační technikou. Všechny takto vyrobené pěny měly propojené póry o velikostech 300 až 2000  $\mu\text{m}$ , celková porozita se pohybovala v rozmezí 50 – 99 %. Pevnost pěn na bázi kalcium fosfátů – 0,3 MPa (při celkové porozitě 80%) byla nedostatečná pro kostní náhrady, kde je požadována pevnost větší než 2 MPa. Kalcium fosfátové keramiky byly tedy zpevněny buďto inertním jádrem na bázi oxidu hlinitého nebo ATZ (oxidem zirkoničitým zhouževnatělým oxidem hlinitým). Dále byl připraven částicový kompozit, ve kterém byl hydroxyapatit pojený oxidem křemičitým. Pevnost pěn se podařilo zvýšit až na více než 20 MPa. V poslední kapitole experimentální části byly studovány keramické pěny pěněné in situ, kde byly póry vytvářeny oxidem uhličitým unikajícím během reakce mezi diisokyanátem a polyalkoholem. Po vypálení polymerního pojiva měly pěny propojené póry o průměrné velikosti 80 až 550  $\mu\text{m}$ . Celková porozita se pohybovala v rozmezí 76 – 99%. Výhodou oproti replikační technice byly plné trámečky bez velké středové dutiny vznikající vypálením polymerní předlohy.

Žádný ze studovaných materiálů nebyl pro buňky toxický, navíc všechny studované pěny vykazovaly bioaktivní chování. Z hlediska kostního tkáňového inženýrství se jako nejslibnější jeví kompozitní materiál zpevněný oxidem křemičitým.
